ABSTRACT: Electrons in solids often adopt complex patterns of chemical bonding driven by the competition between energy gains from covalency and delocalization, and energy costs of double occupation to satisfy Pauli exclusion, with multiple intermediate states in the transition between highly localized, and magnetic, and delocalized, and nonmagnetic limits. Herein, we report a chemical pressure-driven transition from a proper Mn magnetic ordering phase transition to a Mn magnetic phase crossover in EuMn_2P_2 the limiting end member of the EuMn₂X₂ (X = Sb, As, P) family of layered materials. This loss of a magnetic ordering occurs despite $EuMn_2P_2$ remaining an insulator at all temperatures, and with a

phase transition to long-range Eu antiferromagnetic order at $T_N \approx 17$ K. The absence of a Mn magnetic phase transition contrasts with the formation of long-range Mn order at $T \approx 130$ K in isoelectronic EuMn₂Sb₂ and EuMn₂As₂. Temperature-dependent specific heat and 31P NMR measurements provide evidence for the development of short-range Mn magnetic correlations from *T* ≈ 250− 100 K, interpreted as a precursor to covalent bond formation. Density functional theory calculations demonstrate an unusual sensitivity of the band structure to the details of the imposed Mn and Eu magnetic order, with an antiferromagnetic Mn arrangement required to recapitulate an insulating state. Our results imply a picture in which long-range Mn magnetic order is suppressed by chemical pressure, but that antiferromagnetic correlations persist, narrowing bands and producing an insulating state.

■ **INTRODUCTION**

The bonding in solids is often complex, driven by the ability of a multicomponent system to minimize interactions on different length scales through the formation of complex, emergent, states. This gives rise to a variety of exotic and useful electrical and magnetic properties, including charge and magnetic order, charge, and spin density waves, and superconductivity. $1-14$ $1-14$ $1-14$ The precise ground-state configuration of electrons is determined by a subtle interplay between electron−nuclear and electron− electron interactions that is set by the local atomic bonding between atoms. When a material's structure has two distinct magnetic subunits, then the separation of energy scales within and between subunits can give rise to distinct behaviors that would not arise with a single homogeneous magnetic lattice. For example, the coexistence of magnetism and superconductivity in $Ho_2Ni_2B_2C$ arises due to localized 4f magnetism in HoC layers coupled to superconductivity in strongly covalently bonded $Ni₂B₂$ layers.¹⁵ The interactions between subunits can be more directly coupled and depending on the balance of charge and spin interactions, drive subunits to different ground states. For example, the metal $EuFe₂As₂$, which crystallizes in the $ThCr₂Si₂$ crystal structure, exhibits separate magnetic ordering transitions for the anionic

 $(Fe₂As₂)²⁻$ framework and cationic Eu²⁺ layers at ambient pressure.^{[16](#page-6-0)} Under chemical or epitaxial pressure, there is partial additional charge transfer to the $(Fe₂As₂)^{2−}$ framework, which results in superconductivity, with residual weak magnetism in the Eu layers. 16

Separately, triangular lattices of magnetic ions have been intensively studied, with theoretical and experimental findings of classical and quantum spin liquid states that, in the language of chemistry, can best be viewed as the formation of dynamical long-range covalent bonded pairs.^{[17](#page-6-0)−[21](#page-6-0)} In the classical limit, when the magnitude of the single atomic site electron spin is large and isotropic, more complex orders, such as the 120° state as found in RbFe $(MoO₄)₂$, results.^{[21](#page-6-0)} Similar to $RbFe(MoO₄)₂$, which has triangular layers of high-spin Fe³⁺ $(S = 5/2)$, EuMn₂X₂ (X = Sb, As, P) crystallizes in a trigonal CaAl₂Si₂-type structure (space group $\overline{P3}m1$) and has triangular

Figure 1. (a) Heat capacity as a function of temperature for $E u M n_2 P_2$, $E u M n_2 As_2$, and $E u M n_2 S b_2$ single crystals.^{[20](#page-6-0),[23](#page-6-0)} The phase transition close to $T \approx 20$ K is attributed to Eu magnetic order, while the phase transition close to $T \approx 130$ K is attributed to Mn order. Note that the transition attributed to Mn becomes less pronounced going from Sb to As and is absent for EuMn₂P₂. (b) Temperature-dependent heat capacity of EuMn₂P₂ and EuZn₂P₂ single crystals from *T* = 2–300 K. The sharp transition at T_N = 17 K in EuMn₂P₂ and T_N = 21 K in EuZn₂P₂ is attributed to Eu antiferromagnetic order. There is a broad region of excess entropy loss in EuMn₂P₂ from *T* = 100−250 K, suggesting the onset of Mn antiferromagnetic correlations. The inset shows ³¹P NMR, suggesting the formation of a distribution of local magnetic fields on the timescale of the NMR experiment from *T* = 150 K to *T* = 80 K. (c) Change in magnetic entropy, integrated after subtracting the phonons from *T* = 2−300 K. (d) ΔS_{max} from base to *T* = 50 K is close to the *R* ln(8) expected for an *L* = *S* = 7/2 system (i.e., Eu²⁺) at *T* = 17 K, with an additional contribution from Mn at higher temperatures. (e) ¹⁵¹Eu Mössbauer spectra of EuMn₂P₂ single crystals showing the evolution of the spectra with temperature. The solid lines are fits derived either from a full Hamiltonian solution (red line: *T* = 13.75 K) or from the dynamic model (magenta lines), showing the development of Eu order below $T = 17$ K.

layers of Eu²⁺ ($S = 7/2$).^{[22](#page-6-0)} These layers are, however, separated by triangular bilayers of nominally Mn²⁺ ions in $(Mn_2X_2)^{2-1}$ polyanionic subunits. Given the strong covalent bonding expected between Mn and X, and the separation of magnetic energy scales between 3d and 4f magnetism, it is natural to ask: do the Eu and Mn triangular sublattices behave independently, or is there significant coupling between them? If the latter, how do the magnetic orders impact the electronic structure?

To answer these questions, in this work, we investigate the nature of bonding and magnetism in $E u M n_2 P_2$ using a combination of thermodynamic, average, and local probes along with density functional theory (DFT) calculations. The EuMn₂X₂ (X = Sb, As, P) materials are chemically quite different from the AEMn₂Pn₂ (AE = alkali earth, Pn = Pnictogen) compounds since the alkali earth are nonmagnetic and do not interact with the magnetism with the Mn^{2+} spins. While $EuMn_2P_2$ has previously been reported as having magnetic Eu^{2+} cationic layers separated by nonmagnetic $(Mn_2P_2)^{2-}$ polyanionic subunits,^{[22](#page-6-0)} the property of Mn being nonmagnetic in $EuMn_2P_2$ is puzzling since isoelectronic

EuMn₂As₂ and EuMn₂Sb₂ have a phase transition to longrange Mn magnetic order around *T* ~ 130 K.^{[22](#page-6-0)−[25](#page-6-0)}

■ **RESULTS AND DISCUSSION**

Here, we report the discovery of hidden Mn antiferromagnetic correlations developing between *T* = 250 and 100 K via specific heat and ${}^{31}P$ NMR measurements. These short-range correlations are the behavior expected for a system that is transitioning to one with local covalent bonds. The total magnetic entropy associated with the Mn correlations is ∼1/2 that is expected for full ordering and indicates the presence of significant magnetic fluctuations within the $(Mn_2P_2)^{2-}$ layers. No proper phase transition to static Mn order is observed from $T = 2$ K to $T = 700$ K. A-type Eu antiferromagnetic order develops below $T_N = 17$ K and does not seem to be significantly perturbed by the magnetic correlations on Mn, with a phase diagram similar to that of other Eu triangular lattice compounds. However, DFT calculations predict a large (35%, 0.16 eV) reduction in band gap with the development of

Figure 2. Magnetic behavior is isotopic above T_N for Eu with the development of a weak anisotropy (~5%) below T_N . (a) Comparison in the magnetization as a function of temperature for $\mu_0 H || c$ and $\mu_0 H || c$, $T = 2 - 300$ K, (b) anisotropy in the $\mu_0 H || c$ and $\mu_0 H || c$ below T_N , and (c) ratio of magnetization $\mu_0 H$ ||*c* and $\mu_0 H$ \perp *c* at $\mu_0 H$ = 0.[1](#page-5-0) T and *T* = 2–300 K displaying the anisotropy below T_N (ref 1: $\chi(T_N)$ = 0.63 emu/mol). (c, d) Curie–Weiss analysis of EuMn₂P₂ for $\mu_0 H \parallel c$ and $\mu_0 H \perp c$ shows a cusp indicative of magnetic order at $T_N = 17.5(1)$ K. The effective magnetic moment is higher than the theoretical value for Eu^{2+} ($S = 7/2$) and consistent with a small contribution from Mn ions. The measurements of the crystal sample show an excellent agreement with the previous study by Payne et al. 22 22 22 (e) Anisotropy that develops below $T_{\rm N}$. (f) Magnetization as a function of magnetic field with $\mu_{\text{o}}H$ llc from $\mu_{\text{o}}H = -7$ to 7 T and T = 2–25 K, showing a linear response below 3 T, as seen in most Eu
compounds.^{22–[25,27,28](#page-6-0)} Full saturation at 7 $\mu_{\text{B}}/\text{Eu}^{2+}$ is observed as a function of magnetic field with μ_oH llc at intermediate temperatures below T_{N} , e.g., $T = 8$ K. These loops are observed between $T = 6$ and 20 K. (h) Eu magnetic phase diagram of EuMn₂P₂ derived from magnetization as a function of magnetic field at with $\mu_o H$ ||*c*, constructed using the data from (a) and (b) .

Eu magnetic order, attributed to an anomalously large exchange splitting of Mn-d-orbital derived conduction band states. Further, DFT calculations only predict an insulating state when Mn magnetic order is included and is antiferromagnetic. Our results imply a picture for $E u M n_2P_2$ in which long-range Mn magnetic order is suppressed by chemical pressure, but that antiferromagnetic correlations-a prelude to covalent bond formation—persist, narrowing bands and producing an insulating state. This raises the possibility of a novel fluctuating magnetic ground state in EuMn_2P_2 , as well as demonstrating a mechanism by which large exchange splittings of covalent conduction states can be produced in electronic structures by design.

Key evidence for Mn antiferromagnetic correlations and Eu magnetic order are shown in [Figure](#page-1-0) 1. Literature-specific heat measurements for $EuMn₂As₂$ and $EuMn₂Sh₂$, [Figure](#page-1-0) 1a, show two distinct phase transitions: one at $T_N \approx 20$ K associated with Eu ordering, and one at $T_N \approx 130$ K, associated with Mn ordering. In contrast, while EuMn₂P₂ shows a pronounced λ anomaly at $T_N \approx 17$ K with the development of Eu antiferromagnetic order, no anomaly indicative of a magnetic Mn phase transition is observed above $T = 100 \text{ K}^{23-25}$ $T = 100 \text{ K}^{23-25}$ $T = 100 \text{ K}^{23-25}$ Differential scanning calorimetry measurements up to $T = 570$ K ([Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S1) and magnetization measurements up to $T = 700$ K [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S2) also show no evidence for Mn magnetic ordering. One possible explanation for this lack of order would be electron delocalization and a transition to metallic behavior. However, temperature-dependent resistivity ([Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S3) and IR optical conductivity measurements [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S4) both indicate semiconducting/insulating behavior with electrical and optical gaps of 0.2 and 0.68 eV, respectively.

Comparison of the specific heat to the transition-metalmagnetic free analogue $EuZn₂P₂$, [Figure](#page-1-0) 1b, reveals that there is a broad region, *T* = 100−250 K, where there is excess specific heat, and thus excess entropy, in $EuMn_2P_2$. ³¹P NMR, [Figure](#page-1-0) 1b, inset, and [Figures](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S5 and S6, is in agreement with bulk magnetization and shows the development of distribution of local fields and suggestive of the development of Mn magnetic correlations below $T \approx 250$ K. Note that in ³¹P NMR studies, the temperatures below 80 K were not studied due to the scarcity of helium, and the data show a monotonic decrease in the knight shifts. To quantify the magnitude of this excess contribution, an analytical model for the phonon-specific heat in EuZn₂P₂ was constructed and adjusted to account for the mass difference between Mn and Zn, [Table](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) SI and [Figure](#page-1-0) 1c. Subtraction and integration yields magnetic entropy versus temperature, [Figure](#page-1-0) 1d. The entropy recovered from base temperature to $T = 50$ K is 15 J mol⁻¹ K⁻², close to the $R \ln(8)$ $= 17.3$ J mol⁻¹ K⁻² expected for ordering of Eu²⁺ (*S* = 7/2) ions. This interpretation, and the assignment of Eu as divalent $Eu²⁺$, is further confirmed by ¹⁵¹Eu Moessbauer and ZF-NMR, [Figures](#page-1-0) 1e, S7, and S8, and [Table](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) SII, which shows development of Eu magnetic order below $T_N = 17$ K.

In the total entropy, however, there is then a gradual rise over $T \sim 100-250$ K to a value of approximately $R \ln(8)$ + $R \ln(6)$. This excess entropy cannot be from the Eu²⁺ ions, as they are $L = 0$ and there are no low-lying crystal field levels, and thus instead naturally attributed to magnetism on Mn. High-spin Mn would be $S = 5/2$, so we would expect an additional entropy recovery of $\Delta S_{\text{mag}} = 2R \ln(2S + 1) =$ $2R \ln(6)$ [there are two Mn ions per Eu ion]. This is about twice what is observed, suggesting that the Mn^{2+} is not rigorously high spin, that the Mn magnetic lattice is not fully magnetically ordered, or that a more exotic magnetic ground state (e.g., a quantum spin liquid) is present, all of which are in agreement with magnetization measurements (vide infra).

Figure 3. (a) EuMn₂P₂ crystallizes in space group *P*3*m*1, no. 164. The crystal structure consists of anionic framework on $(Mn_2P_2)^{2-}$ with tetrahedral framework and Eu²⁺ cations occupying the corner sites. (b) Picture of grown single crystal of EuMn₂P₂. (c) Predicted intermediatetemperature magnetic structure with C-type antiferromagnetic order of Mn. (d) Predicted low-temperature magnetic structure with the same Mn ordering and A-type antiferromagnetic order of Eu and enlargement of the unit cell. (e) Electronic band structure and density of states within GGA + *U* following the magnetic structure as shown in (c). As expected from the bonding framework, the states near the Fermi level (*E*^f) are coming from Mn-d states, whereas the Eu-f states are further away from the $E_{\rm f}$. Calculations with nonmagnetic Mn, or ferromagnetic Mn, predict a metallic/ semimetallic state, at variance with experiment (see the Supporting [Information](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf)). (f) Density of states (DOS) associated with the band structure in (d), showing a predicted band gap of 0.45 eV. (g) Electronic band structure and density of states within GGA + *U* following the magnetic structure as shown in (d) , which includes Eu magnetic order. (h) DOS associated with the band structure in (f) , showing a large exchange splitting reduction of the band gap to 0.29 eV.

Inspection of individual heating pulse traces showed no sign of latent heat that would indicate a first-order phase transition.

To explore the magnetic properties of $EuMn_2P_2$ in greater detail, magnetization as a function of temperature and magnetic field is shown in [Figure](#page-2-0) 2. *M*(*T*) plots show a clear antiferromagnetic phase transition at $T_N \approx 17$ K with a sharp peak in the magnetization followed by an unusual flat plateau below T_N , as seen in [Figure](#page-2-0) 2a. We also observe signatures of anisotropy below T_N . It is easier to polarize the spins along the *c*-direction than the *a*−*b* plane, which suggests that the c direction is the easy axis in $EuMn_2P_2$, [Figure](#page-2-0) 2b. Figure 2c,d shows Curie−Weiss analysis of magnetic susceptibility for the two field directions. With $\mu_0 H$ ||*c*, a Curie constant per formula unit of $C = 9.0$ emu K mol·f.u.⁻¹ Oe⁻¹ and a positive Weiss temperature of 9.0 K are found. The Curie constant is larger than the expected value for pure high-spin Eu^{2+} (*S* = 7/2), *C* = 7.8 emu K mol·f.u.⁻¹ Oe⁻¹, suggesting a contribution of ~1 emu K mol·f.u.[−]¹ Oe[−]¹ from Mn. This is much less than the extra 2·4.3−8.6 emu K mol·f.u.[−]¹ Oe[−]¹ that would be expected from high-spin Mn^{2+} . It is, however, consistent with the strong covalent bonds in the Mn−P framework that are known to reduce magnetic moments^{[27](#page-6-0)} and suggestive of the existence of Mn antiferromagnetic correlations over the region of the fit, *T* = 50−300 K. With *μ*0*H*⊥c, similar values are found: a Curie constant per formula unit of $C = 8.91$ emu K mol·f.u.⁻¹ Oe⁻¹ and a positive Weiss temperature of 8.8 K are found. This is consistent with an isotropic magnetic response above the Eu

ordering temperature, [Figure](#page-2-0) 2e. The Mn contributions from Curie–Weiss analysis are also not seen in SrMn₂P₂ and CaMn₂P₂. The $M(H)$ behavior in the low-temperature region with μ_0 *H*||*c* is shown in [Figure](#page-2-0) 2f. Below T_N , the magnetization is nearly linear with applied magnetic field until saturation is reached. Such behavior is seen in many Eu compounds.[20](#page-6-0)−[25](#page-6-0),[27](#page-6-0)−[29](#page-6-0) No excess magnetization attributable to Mn is observed. This implies that Mn has strong antiferromagnetic correlations. More detailed inspection shows that there are small but systematic "open" hysteresis loops that appear prior to saturation, [Figure](#page-2-0) 2g. There are two noticeable attributes to this result: (a) this plot is reproducible, (b) it follows a behavior one would expect for a ferromagnetictype state. These results are consistent with an antiferromagnetic ground state at zero field that arises from coupled ferromagnetic planes of Eu^{2+} ions. This agrees with previous findings from neutron diffraction.[22](#page-6-0) [Figure](#page-2-0) 2h summarizes the magnetic phase diagram extracted from these data.

We use density functional theory (DFT) within GGA + *U* to explore the electronic structure and bonding of $EuMn_2P_2$ and how it might be impacted by the observed magnetic behaviors. EuMn2P2 crystallizes in a trigonal lattice ([Tables](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) SIII−SV and Figure 3a). Calculations with A-type antiferromagnetic order and a Hubbard U (to account for the strong Pauli repulsion in open shell f systems) on the Eu atoms, to match known Eu magnetic behavior, 22 22 22 and along with nonmagnetic Mn predicts metallic behavior, in disagreement with experiment. Indeed,

the Mn d-orbitals dominate the Fermi level, [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S9a, as expected for Mn, which has a partly filled d-orbital manifold. However, introducing magnetism on Mn by either setting an antiferromagnetic Mn order without a Hubbard U or Mn ferromagnetic order with a Hubbard U also results in metallic behavior [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S10). It is only when a Hubbard U and antiferromagnetic order on the Mn ions is included that semiconducting behavior is predicted, [Figure](#page-2-0) 2c,e,f. Inclusion of spin−orbit coupling (SOC), [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S11, has a negligible effect on the band structure and symmetry analysis confirms that the compound is a topologically trivial insulator. These results suggest that the band narrowing associated with Mn antiferromagnetic exchange plays a pivotal role in opening a band gap—this is exactly the behavior expected to occur in the formation of covalent metal−metal bonds and suggests that $EuMn_2P_2$ is on the verge of forming such bonds.

As the states near E_f are dominated by Mn in the $(Mn_2P_2)^{2-1}$ layers, this necessitates a proper understanding of the behavior of Mn. By computing the energy of different antiferromagnetic configurations, we can use DFT to predict the intermediatetemperature and low-temperature magnetic configurations of this material, including both Mn and Eu magnetism. Since the SOC is negligible, we consider A-type, C-type, and G-type antiferromagnetic configurations for Mn. For the intermediatetemperature configuration, we set the Eu f-orbitals in the core and we find that the C-type configuration, [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S12, is the lowest in energy. Such assignment is in agreement with the observation of a sharp magnetic phase transition when Eu orders below $T = 17$ K because of lowering in the symmetry that would be predicted when Eu orders. In contrast, the closein-energy G-type Mn order would have resulted in a crossover instead of transition for Eu magnetic ordering, as there would no longer be a change in symmetry. The C-type magnetic structure for Mn is also observed in the isostructural analogue $EuMn₂As₂$, and thus this arrangement likely best describes the local ordering in EuMn_2P_2 .^{[23](#page-6-0)–[25](#page-6-0)}

The corresponding band structure and density of states with Mn magnetic order and Eu in the core, [Figure](#page-2-0) 2e,f, give a small indirect band gap, ∼0.45 eV. This indirect gap decreases significantly to ∼0.29 eV when Eu magnetic order is considered due to exchange splitting of the conduction band states, [Figures](#page-2-0) 2g,h and [S9b](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf). In both cases, the direct gap is markedly larger, ∼1.3 eV. These gaps agree with roomtemperature optical reflectivity measurements, [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S4, which shows a tail of absorption down to ∼0.2 eV with a sharp edge at ∼0.7 eV, and also in agreement with temperature-dependent resistivity measurements, [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S3. Such a large change in indirect gap, with a correspondingly large splitting of conduction band states at the conduction minimum, would be expected to give rise to novel electrical behavior, and in particular nonlinear IV curves, [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S13. And indeed, there is development of a nonlinear IV response close to the Eu magnetic ordering transition, [Figures](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S14−S17, [Tables](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) SVI, and SVII. However, thermomagnetoelectric finite element simulations with realistic materials parameters and dimensions, [Figure](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) S18, show that the nonlinearity likely arises due to Joule heating, and is not directly associated with changes in the intrinsic electronic structure and bonding.

It is natural to ask why $EuMn_2P_2$ behaves differently from $EuMn₂As₂$ and $EuMn₂Sb₂$. Not only does the former not show a proper Mn magnetic phase transition, but the latter are found to exhibit metallic (or very heavily doped semiconductor) conductivity. The bond distances between Mn−X (*X* = P, As,

and Sb) increase as the ionic radius of X becomes larger, [Figure](#page-1-0) 1a. Combined with an increase in the difference in electronegativity, this reduces the covalency of the $(Mn_2X_2)^{2-1}$ network and results in more "ionic" behavior from the Mn cations, [Table](https://pubs.acs.org/doi/suppl/10.1021/jacs.2c11324/suppl_file/ja2c11324_si_001.pdf) SVIII. This explains the more definitive magnetic transitions from $X = P$ to As and Sb. At the same time, the valence and conduction bands become broader going from $X = P$ to $X = Sb$ due to larger orbitals on the anions, which reduces the gap and explains the higher metallicity.

■ **CONCLUSIONS**
In summary, we report the discovery of suppression of a longrange magnetic ordering phase transition in favor of a crossover with the development of Mn antiferromagnetic correlations in $EuMn_2P_2$. The property Mn not having a phase transition in $E u Mn₂P₂$ is surprising since isoelectronic $EuMn₂As₂$ and $EuMn₂Sb₂$ have Mn magnetic order phase transitions, but can be understood as chemical pressure favoring local antiferromagnetic correlations that are prelude to the formation of proper metal−metal covalent bonds. We also predict that there is a substantial exchange splitting of $(Mn_2P_2)^{2-}$ states with the occurrence of Eu magnetic order. Our results provide evidence for rich bonding and changes in electron behavior in $EuMn_2P_2$ and should open avenues to study other Mn materials for realizing complex bonding between covalent and magnetic orders.
